scanning a different version of the project, purposely full of known vulnerabilities.

That’s it for this chapter. Next, I’ll cover one of the main cloud native development practices: externalized configuration.

Summary

- Each cloud native application should be tracked in its own codebase, and all its dependencies should be declared in a manifest using tools like Gradle or Maven.
- Cloud native applications don’t depend on servers being injected into the environment. Instead, they use an embedded server and are self-contained.
- Tomcat is the default embedded server for Spring Boot applications, and it can be configured through properties to customize the ports it listens on, connections, timeouts, and threads.
- The request/response interaction provided by a Servlet container like Tomcat is both synchronous and blocking. Each thread handles an HTTP request until a response is returned.
- The API first principle recommends designing the API before implementing the business logic to establish a contract. In this way, other teams can develop their services to consume your application based on the contract itself, without waiting for the application to be finished.
- In Spring MVC, REST APIs are implemented in `@RestController` classes.
