State management options	Use `useState`, `useReducer`.	Apply Context API effectively.	Architect advanced state management solutions with Redux (https://redux.js.org), MobX (https://mobx.js.org), Zustand (https://zustand.docs.pmnd.rs), Jotai (https://jotai.org), or Recoil (https://recoiljs.org).
Context API	Share state globally without props.	Combine with useReducer for complex global state.	Optimize context re-renders, split contexts for performance.

Understanding React's data flow, let's explore some sample interview questions.

Initial question (fundamental skill): "Can you explain how one-way data binding works between parent and child components in React?"

Analysis: This question evaluates understanding of React's core data flow principles, specifically unidirectional (one-way) data binding. It assesses the ability to clearly explain how data moves from parent to child components using props, why this approach is favored for predictability and maintainability, and how React's architecture supports these goals.

Answer: React uses one-way data binding, or unidirectional data flow, where data moves from parent components down to child components. This design makes state changes predictable, simplifies debugging, and improves maintainability by preventing child components from directly modifying parent state.

In this model, the parent acts as the source of truth, holding state and passing it down as props along with updater functions. Child components receive state as read-only props and trigger changes by calling the parent's updater. React then updates the state, runs reconciliation, and re-renders the parent
