- You should terminate the `ActorSystem` so the system can gracefully shut down all running modules that hold, for example, HTTP or DB connections.
- The operator `tell`—in its short form, the bang (`!`) operator—allows you to send messages to an actor.
- For each message that an actor processes, you need to define the behavior for the next message. Thanks to this abstraction, you only have to worry about processing a single message at a time, eliminating a whole dimension of concurrency problems.
- Behaviors are nested to form the complete behavior of an actor just as functions are chained, where the output of one function is the input of the next.
- Multiple messages usually form the protocol of the actor. They are the actor's API and the only way another actor can communicate with it.
- An actor can store its state two ways: as a value in its constructor by adding a variable that can be updated when messages are received, or as a behavior by creating multiple behaviors that respond differently to the same messages. This arrangement is also called a finite state machine.
- `Behaviors.withTimers` allows you to schedule messages by specifying when and how often the message should be sent.
