On the Akka side, we can see how `BehaviorTestKit` is used to create a test kit that you use as an interface to interact with the actor. For each assertion with `expectEffect`, you can check whether an effect exists by polling from a queue in the test kit's stubbed context. This mechanism enables determinism—a stubbed context with a queue.

This type of testing is about stubbing. There is no real `ActorSystem` but only a dummy `ActorSystemStub`. When you use `Spawn` or any other action that belongs to the actor's context, an effect representing this action is created and stored in a queue that you can later retrieve with `testKit.expectEffect`.

The context itself (`ActorContext`) is a `StubbedActorContext` that mocks methods such as `spawn`, `stop`, and `scheduleOnce` and stubs values such as `Children`, `Self`, and `System`. All of this is available after the creation of the `BehaviorTestKit`. This process is illustrated in figure 4.1.
