Summary

- The `BehaviorTestKit` can test an actor in isolation, but it cannot test scheduling or asynchronous calls in code. It is built by mocking an `ActorSystem` by creating queues to store the effects of messages sent to the actor. This allows you to implement a white-box testing style.
- With the `ActorTestKit`, there are no restrictions for testing scheduled messages or asynchronous calls. It creates a real `ActorSystem`. Messages sent to an actor can run in parallel and arrive in an undetermined order. This allows you to implement a black-box testing style.
- You can extend your test class with `ScalaTestWithActorTestKit` to avoid creating the `ActorTestKit` and shutting down the `ActorSystem` after all tests.
- `Behaviors.monitor` lets you monitor a real actor with a probe. Every message sent to the actor is also sent to the probe, which you can use to test expectations.
- To determine whether your actor received a particular message, you can fish for message types using a probe from the `ActorTestKit`. This way, you can determine what to do depending on the captured message: keep or discard the message, continue or stop fishing, or fail the test.
