❹ Seed nodes of the cluster

Keeping the addresses exactly the same

You see 127.0.0.1 and not `localhost` in listing 8.1 because the latter might resolve to a different IP address, depending on your setup, and Akka interprets the addresses literally. You can't depend on DNS resolution for the `akka.remote.artery.canonical.hostname` value that is used exactly for the system's address; no DNS resolution is done on it. The exact value of the address is used when actor references are serialized between Akka remote nodes. So, once you send a message to the remote actor referred to by such an actor reference, the remote actor will use that exact address to connect to the remote server.

The primary reason not to use DNS resolution is performance. DNS resolution, if configured incorrectly, can take seconds—or minutes, in a particularly bad case. Determining that delays are caused by an incorrect DNS configuration is not easy, and the problem usually is not immediately apparent. Not using DNS resolution avoids this problem, but it means you have to be careful when configuring the addresses.

`remote.artery` refers to the remoting implementation: `artery` is a reimplementation of the classic Akka module for node intercommunication that provides, among other things, better performance and reliability. `artery.transport` provides three protocols:

- `tcp`—The default setting. It is based on Akka Streams TCP, which provides high throughput and low latency.
- `tls-tcp`–The same as `tcp` but with encryption using Akka Streams TLS.
