Next, set node discovery on the deployment.

Listing 13.3 Setting the labels to discover the nodes belonging to the Akka cluster

```
apiVersion: apps/v1
kind: Deployment
...
spec:
...
  selector:
    matchLabels:
     app: testing-bootstrap13babc                          ❶
...

  template:
    metadata:
      labels:
        app: testing-bootstrap13babc                       ❶
        actorSystemName: testing-bootstrap13b
    spec:
...
        env:
        - name: AKKA_CLUSTER_BOOTSTRAP_SERVICE_NAME        ❷
          valueFrom:
            fieldRef:
              apiVersion: v1
              fieldPath: "metadata.labels['app']"
```

❶ Must be the same for Kubernetes to recognize them as belonging to the cluster

❷ Environment variable that Akka reads to find the labels that are part of the cluster

Filtering by label

The `template.metadata.label` property belongs to the pod and can be used like any other label to group pods so you can perform bulk actions on them. For example, you can filter using the `get` action: `kubectl get pod -l app=testing-bootstrap13babc`. If you can filter with `template.metadata.label`, why is `selector .matchLabels.app` needed? This has little to do with Akka; it is purely a Kubernetes requirement used to relate the deployment to the pods, and they need to have the same value.
