The database projection does two things. On the one hand, it creates a row in a table that links the bet, market, and wallet. Each time the journal receives a `BetOpened`, a record is upserted with the following fields:

```
betId, walletId, marketId, odds, stake, result
```

On the other hand, a query is created to this table, which retrieves how much money the betting company has to return to the users for a market, depending on the result. For example, the market for the Liverpool vs. Real Madrid soccer match may look like this:

```
0 - $100000    ❶
1 - $90000     ❷
2 - $100       ❸
```

❶ Money to give back if Liverpool wins

❷ Money to give back if Real Madrid wins

❸ Money to give back in case of a draw

This query is provided as a gRPC service and helps with risk management. An operator can retrieve this information via HTTP and set a cap for a particular market if the return becomes too risky for the house.

The following listing shows these two actions in the `repository` implementation.

Listing 15.1 Repository actions in the database projection

```
class BetRepositoryImpl extends BetRepository {

  override def addBet(
      betId: String,
      walletId: String,
```
