Now you can create wallets, markets, and bets and check how the projections in the database and Kafka are populated. There are examples to follow in the README.md to interact with the application.

Summary

- The betting database projection was made accessible via an HTTP server by creating a query to access the result of the projection, using the same repository of the betting projection, and providing access to this query via the HTTP server.
- The events of the market were written into Kafka by creating a Kafka projection so they can be consumed by any process—for example, to settle the bets when a market is closed.
- You can run the betting house locally and in Kubernetes with almost the same configuration. The only major differences are the use of seed nodes in local and the use of Akka Cluster Bootstrap and Akka Management in Kubernetes.
- To deploy the application in Kubernetes, package it into a JAR and then into a Docker image. In the Kubernetes cluster, set the `Role`, `RoleBinding`, namespace, database, Kafka cluster, and `Deployment`.
