```
dropped 10
processed 4
processed 6
processed 8
processed 10
processed 12
```

Here you can see which items are queued and which are dropped. For a client pushing data into a stream, it can be important to check whether an item was dropped so it can try to offer the item again.

Summary

- Elements can be efficiently transformed depending on whether the service is CPU-bounded. `mapAsync` provides more parallelism when the service is not CPU-bounded, and `mapAsyncUnordered` provides more performance when the processing time per element has a high variance.
- You can call a database or HTTP endpoint within the stage of a stream with any `*Async` operator. You can use the previous stage as input for the call and the following stage for processing the response.
- Stream from an actor using `ActorFlow.ask` to ask the actor and process the response in the next stage.
- Add elements to an already-running stream using `Source.queue`. With this operator, you can keep a reference to the source to add elements anytime and anywhere in your application.
