- An alternative is to register a portion of the path on the web domain of the app producer. For example, your app could register with the operating system that it will handle all requests to `https://example.com/app/callback`. When the AS redirects to this HTTPS endpoint, the mobile operating system will launch the native app just as for a private-use URI scheme. Android calls this an *App Link* (https://developer.android.com/training/app-links/), while on iOS they are known as *Universal Links* (https://developer.apple.com/ios/universal-links/).

A drawback with private-use URI schemes is that any app can register to handle any URI scheme, so a malicious application could register the same scheme as your legitimate client. If a user has the malicious application installed, then the redirect from the AS with an authorization code may cause the malicious application to be activated rather than your legitimate application. Registered HTTPS redirect URIs on Android (App Links) and iOS (Universal Links) avoid this problem as an app can only claim part of the address space of a website if the website in question publishes a JSON document explicitly whitelisting that app. For example, to allow your iOS app to handle requests to https://example.com/app/callback, you would publish the following JSON file to `https://example.com/.well-known/apple-app-site-association`:

```
{
  "applinks": {
    "apps": [],
    "details": [
```
