```
post("/spaces", spaceController::createSpace);
```

Finally, as all our API responses will be JSON, we add a Spark `after` filter to set the Content-Type header on the response to `application/json` in all cases, which is the correct content type for JSON. As we shall see later, it is important to set correct type headers on all responses to ensure that data is processed as intended by the client. We also add some error handlers to produce correct JSON responses for internal server errors and not found errors (when a user requests a URI that does not have a defined route).

> **TIP** Spark has three types of filters (figure 2.4). Before filters run before the request is handled and are useful for validation and setting defaults. After filters run after the request has been handled, but before any exception handlers (if processing the request threw an exception). There are also afterAfter filters, which run after all other processing, including exception handlers, and so are useful for setting headers that you want to be present on all responses.
