connections from the ingress to backend services are also protected with mTLS.

[1] The root group has a GID of 0 but, unlike the root user, membership of the root group doesn't grant superuser privileges. Often files created by the root user are readable by members of the root group though.

[2] Some older versions of Java would replace references to /dev/urandom with /dev/random on the mistaken assumption that this was more secure. This behavior has been fixed in recent versions, but if you need to use an older version you can use the string `file:/dev/./urandom` to get around this broken behavior.

[3] Restarting minikube will also delete the contents of the database as it is still purely in-memory. See https://kubernetes.io/docs/concepts/storage/persistent-volumes/ for details on how to enable persistent disk volumes that survive restarts.

[4] At the time of writing most service meshes don't support certificate revocation, so you should use short-lived certificates and avoid relying on this as your only authentication mechanism.

[5] Istio has more features that Linkerd but is also more complex to install and configure, which is why I chose Linkerd for this chapter.

[6] The exception is the H2 database as Linkerd can't automatically apply mTLS to this connection. This should be fixed in the 2.7 release of Linkerd.
