These steps are repeated till there is only 1 element left in the queue (figure 2.17 shows a few more steps), and that last element will be the `TreeNode` that is the root of the final tree.

We can then use it, in line #12, to create a compression table, which will be the final output of the `huffman` method. In turn, the compression table can be used to perform the compression of the text by translating each one of its characters into a sequence of bits.

While we won't show this last step[19], we provide listing 2.15 with the steps needed to create a compression table from the tree in figure 2.15; while this goes beyond the scope of this chapter (since the method doesn't use a priority queue), providing a brief explanation should help those readers interested in writing an implementation of Huffman coding.
