(or internal ID) of the company, and its domain[10] is relatively small[11], we can easily identify the intermediate results we need and we can expect to reuse them several times. If our application runs for long enough without restarting, after an initial warm-up period when we have to actually compute values (and hence latency will be high during this warm-up), we will have computed enough intermediate results to respond to calls *quickly*, without the extra latency due to the external HTTP calls.

Take a look of how these assumptions change our architecture in figure 7.2, and meet the cache, our knight in a shiny armor that will save us from failing our SLA and going out of business.
