```
      if e.dest == u
then                                                    #7
        return true
    return false
```

#1 When we add a new vertex, provided it's not a duplicate, we first need to add it to the vertices list.
#2 But we also want to initialize the adjacency list for the new vertex: it will simplify our life later!
#3 Check if the vertices are adjacent, i.e. if there is already an edge from v to u.
#4 If so, remove the old one first (this method is omitted, but can be derived from `areAdjacent`).
#5 Add a new edge, created based on the arguments, to the adjacency list for the source vertex.
#6 Iterate through all edges in the adjacency list for the source vertex.
#7 As soon as it finds an edge whose destination is matching u, we can return true. If none matches, the vertices are not adjacent.

As for concrete implementation, a Java version can be found on the book repo, and a JavaScript version can be found here; the latter will also implement the algorithms described in the next sections.

14.2 Graph Properties

As we mentioned, graphs are very similar to trees. They are both made of entities (vertices) connected by relations (edges), with a couple of differences:
