```
        public void OnPost()
        {
            Country = new Country                          ❹
            {                                              ❹
                CountryName = Input.CountryName,           ❹
                CountryCode = Input.CountryCode            ❹
            };                                             ❹
        }

        public class InputModel                            ❺
        {
            public string CountryName { get; set; }
            public string CountryCode { get; set; }
        }
    }
}
```

❶ Add a using directive to bring in the CityBreak.Models namespace.

❷ Add the input model and a property, and make it a binding target by adding the BindProperty attribute.

❸ Add a Country property to the PageModel.

❹ Instantiate the Country property from the properties of the InputModel.

❺ Declare a class that encapsulates the fields for the country entry form. This is the input model.

The `InputModel` class is declared *within* the `PageModel` class, so it is a *nested* class. This limits its scope to the current `PageModel`, thereby allowing you to use the same name (`InputModel`) for classes that act as binding targets on other pages.

The key to binding complex objects is to ensure that the `name` attribute of the input is in the form `<property>.<property>`, where the first `property` is the name of the complex `PageModel` property (the input model) that has the `BindProperty` attribute applied, and the second `property` is the name of the property in the input model class, as shown in figure 5.6.
