6.2 Input and label tag helpers

In the last chapter, you progressed from the potentially error-prone practice of mapping the names of form field controls to keys in the `Form` and `Query` collections to binding to public properties that are explicitly marked as binding targets due to having the `BindProperty` attribute applied to them. But you still have room for error because the value of the control's `name` attribute must match the target `PageModel` property's name. Recall the HTML for the form in the city's Create page, where you assign the string `"cityName"` to the `name` attribute:

```
<input class="form-control" type="text" name="cityName" />
```

As discussed previously, you cannot rely on strings matching. A change to one or the other will only result in errors at run time. Since the properties are accessible within the Razor page, it is possible to use the `nameof` expression directly in your Razor code to ensure the generated value for the form control's name attribute matches the property name:

```
<input name="@nameof(Model.CityName)" type="text" />
```

However, using an input tag helper achieves something similar with less ceremony and offers more bang for your buck. It has a `for` attribute that takes the name of the `PageModel` property and effectively binds that property to the tag helper, generating both a `name` and an `id` attribute in the rendered HTML for the form control. The input tag helper will also render the `type` attribute, setting its value to a suitable one based on the data type of the bound property, so you don't need to include that in your markup either. And the tag helper also renders a `value` attribute, which is
