there is no `Password` type in .NET, but you can specify that a string should be considered a password type through data annotation attributes. Most of the framework ignores this metadata, but the input tag helper will respond to it by setting the `type` attribute on the rendered control to `password`. A browser will render an input that has its type set to the password as a form control that obscures the characters being entered by default as a security measure.

The `DataType` attribute has two constructors. One takes a `DataType` enumeration value, and the other takes a string. A wide range of enumeration values are available, but only a subset influences the generated type on an HTML input. They are detailed in table 6.2.

**Table 6.2 Mapping between `DataType` enumeration and input type**

| `DataType` enumeration | Input element's type attribute |
|---|---|
| `Date` | `date` |
| `EmailAddress` | `email` |
| `Password` | `password` |
| `PhoneNumber` | `tel` |
| `Time` | `time` |
| `Url` | `url` |

When you apply multiple attributes to a property (e.g., the `BindProperty` attribute and a `DataType`) you can apply them individually within their own set of square brackets or use one set of brackets and separate each attribute with a comma. Both of the examples in listing 6.5 are valid.

**Listing 6.5 Different options for applying multiple attributes to a single property**
