You've done a lot of work with forms over the last couple of chapters, which will stand you in good stead when you create your own applications. Previously, you looked at how to use the Razor syntax to generate dynamic content and how to surface your pages through routing. So you have covered a lot in terms of your application's presentation layer.

In the following few chapters, you will start to look at the logical components of your application: its services. The next chapter looks at what a service is and how services are managed in an ASP.NET Core application. Beyond that, you will start looking at the services provided by ASP.NET Core for managing data and users.

Summary

- The form and form action tag helpers generate URLs for form submission.
- The form tag helper generates a hidden input containing the request verification token.
- Input tag helpers generate different `type` attributes in response to the data type of the model property bound to them. They also generate `data-val` attributes for client-side validation.
- You can use the `DataType` attribute on model properties to generate more specific `type` attributes.
- The label tag helper renders the raw property name by default. You can use the `Display` attribute to render something more user friendly.
- The select tag helper targets the HTML select element. It renders the options bound to it via its `items` attribute.
