retrieving the details from the database. The data is sent to the service layer (see the gray arrows) and then on to the Razor page, where it is merged with the view template (the one with the @ sign) to create HTML. The generated HTML is passed via the app out to the web server to be returned to the client.

As well as providing solutions to functional requirements, frameworks typically offer a standard way to build and deploy applications. They might encourage you to adopt proven software design patterns when building your application to make the result easier to test and maintain.

In essence, web development frameworks can speed up the process of developing web applications by providing prebuilt and tested solutions to common repetitive tasks. They can help you produce consistent results by encouraging you to work to a set of standards.

1.1.2 Server-side frameworks

Next, we'll take a look at what it means when we say Razor Pages is a server-side framework. When developing dynamic web applications, you must decide where your HTML is generated. You can choose to generate HTML on the user's device (the client) or on the web server.

Applications that generate HTML on the client, or single-page applications (SPAs), are restricted in terms of the technologies that can be used. Up until recently, you could only really use JavaScript to create these kinds of applications. This has changed since the introduction of Blazor, which enables you to use C# as your application programming language. To learn more about this, see Chris Sainty's *Blazor in Action* (Manning, 2021). Since most of the application processing takes place on the user's device, you have to be mindful of its resources, which you have no control over. You also
