into the `CreateModel` class to alter the `GetCityOptions` method. In other words, a change of data access strategy currently provides an additional reason for changing the `PageModel` class. If you are to comply with SRP, you need to move the logic that generates the city data into its own component with the single responsibility of managing data for the `City` entity.

Think back to the don't repeat yourself (DRY) principle discussed in chapter 3, which encourages you to minimize code duplication. *Each piece of logic should only have one representation in the system*, the principle states. We have fallen foul of this principle too. We have code in the home page that generates cities for the list box example, effectively duplicating the `GetCityOptions` code just discussed in the `CreateModel`. This code should be centralized, and once again, moving it to its own component will address the fault.

Let's start by fixing this. You will build a component with the responsibility of generating a collection of `City` objects and making that available to any part of the application that needs it. Then you will use that component in the `PageModel` class to provide the source data for one of the select lists you have built so far.

Start by adding a new folder named Services to the root of the application. Within this, add a new C# class named SimpleCityService.cs. The content of the file is provided in the following listing.

Listing 7.1 The `SimpleCityService` code

```
using CityBreaks.Models;

namespace CityBreaks.Services
{
    public class SimpleCityService
    {
```
