8.1.5 Create the context

The entry point to working with EF Core in code is the *context*—an object derived from `DbContext`. It represents a session with a database and provides an API for communicating with the database to perform data operations, such as querying and data persistence. It also supports more advanced features, such as model building and data mapping, which we will touch on later, as well as transaction management, object caching, and change tracking, which aren't be covered in this book.

The steps required to deliver a working context to the application are

1. Create a class that derives from `DbContext`.
2. Provide a connection string.
3. Register the context with the service container.

Starting at step 1, add a new folder to the project named Data, and within that, add a new class file named CityBreaksContext.cs with the following code.

Listing 8.5 The `CityBreaksContext`

```
using Microsoft.EntityFrameworkCore;

namespace CityBreaks.Data
{
    public class CityBreaksContext : DbContext
    {
        public CityBreaksContext(DbContextOptions options) : base(options)
        {

        }
```
