```
    public async Task<Property> CreateAsync(Property property)
    {
        _context.Add(property);
        await _context.SaveChangesAsync();
        return property;
    }

    public async Task<Property> UpdateAsync(Property property)
    {
        _context.Update(property);
        await _context.SaveChangesAsync();
        return property;
    }
}
```

The first method uses the `FindAsync` method to retrieve a single entity. This method is different from the methods that begin with `First` and `Single` you have looked at so far. It takes a value representing the key of the entity to retrieve, but you cannot use it with the `Include` method. When you edit an item, you don't necessarily need its associated data; you only need the foreign key values. The `FindAsync` method is perfect for this purpose.

The `CreateAsync` method uses the `DbContext.Add` method to get the context to begin *tracking* the property entity. An `EntityState` is applied to all entities tracked by the context, which is an enumeration specifying the entity's current state. When you use the `Add` method, the `EntityState.Added` value is assigned. This tells the context that the entity should be added as a new record, and the generated SQL is an `INSERT` statement.

The `DbContext.Add` method was introduced in EF Core. In previous versions of EF, data operations were performed against the relevant `DbSet`, with the equivalent being

```
_context.Properties.Add(property)
```
