- The main entry point to working with EF Core is via a context, an object that derives from `DbContext`.
- The EF Core context tracks objects and generates SQL based on their state.
- Entities map to database tables via `DbSet` objects.
- EF Core translates LINQ queries to SQL, which it executes against a database.
- Conventions drive EF Core mappings between objects and the database.
- You can customize the mapping using configuration.
- EF Core migrations enable you to keep your model and database schema in sync with each other.
- You can use seeding to add data to the database as part of a migration.
- Scaffolding enables you to quickly generate CRUD pages based on EF Core’s mappings.
