The 400 HTTP status code represents a malformed client request. In Razor Pages, this error occurs most commonly because a `POST` request is missing a request verification token. If you recall from chapter 6, the token is generated as a hidden field when the form tag helper has its `method` set to `post`. If you check the code you added in listing 11.10, there is no `method` attribute on the form element; hence, the hidden input was not generated.

The fix is straightforward in this case. You just add `method="post"` to the form element and rerun the application. The hidden field will be generated and will be included in the serialized values posted to the server. However, it is not uncommon to have no form element at all when you post values with AJAX. You might want to post the result of a calculation, for example, rather than the content of a form field. So in those cases, what are your options?

First, you could consider disabling request verification. This has to be done at the `PageModel` level by adding the `IgnoreAntiforgeryToken` attribute on the handler class. You cannot disable request verification at the page handler level (unlike an MVC action method), so if you have other handlers on your page that process `POST` requests, you will disable request verification for those too. That is probably not acceptable, and disabling this security feature is generally not advisable anyway. That leaves you with generating a token value and including it within the AJAX request.

You can render a hidden input with a token value using the `AntiForgeryToken` method on the `Html` helper property of the Razor page:

```
@Html.AntiForgeryToken()
```
