```
            }
        };
        fetch('?handler=booking', {
            method: 'post',
            headers: {
                "Content-type": "application/json",                ❶
                "RequestVerificationToken" : token                 ❷
            },
            body: JSON.stringify(data)                             ❸
        }).then((response) => {
            return response.json();                                ❹
        }).then((result) => {
            alert(`Your stay will cost ${result.totalCost}`);      ❺
        });
    });
```

❶ You must specify the content type as application/json.

❷ You must pass the request verification token as a request header.

❸ Use the JSON.stringify method to serialize your JavaScript object to JSON format.

❹ Use the json method on the response, which parses the return JSON into an object.

❺ Access the totalCost property of the resulting object.

Note that the header's name for the token does not have leading underscores. If you get a 400 error code when working with JSON, check the header's name once you have checked it is present. If you don't specify the content type as `application/json`, it will default to `text/plain`, and your handler will error because it will not attempt to parse the request body.

The jQuery version (listing 11.17) uses the `ajax` method rather than the shorthand `post` method to request because the `ajax` method enables you to set headers. The request's content type is specified using one of the `contentType` options in the settings rather than explicitly setting a header value.
