The recommended version of Serilog for ASP.NET Core application logging is Serilog.AspNetCore (http://mng.bz/M0WB). So use your preferred method for installing that package from NuGet. Your project file should be updated with a new package reference accordingly, although the version number might differ:

```
<PackageReference Include="Serilog.AspNetCore" Version="4.1.0" />
```

CONFIGURATION

Serilog recommends the logger to be configured prior to the `WebApplication .CreateBuilder` method call in Program.cs, so it can log any application startup errors. Serilog supports two configuration strategies:

- You can use the appSettings.json file to configure Serilog, just as you have done with the default logging.
- Alternatively, you can use a fluent API. This is the recommended approach and the one that you will adopt in the chapter.

The main reason for recommending the fluent API approach is the appSettings.json configuration is not available until after the `WebApplication.CreateBuilder` method has been called. If you want to use appSettings.json for logging configuration, you will either need to create two loggers—one for application start (that will use the fluent API anyway) and another that reads its config from appSettings.json after the `Create-Builder` call—or create just one logger and forego logging details of application start errors.

To begin, you will add three additional `using` directives at the top of the Program.cs file, the first of which you will always need when working with
