```
    </div>
</div>
```

❶ The cache tag helper wraps the content to be cached.

When you first run the application, the view component is invoked, the data is retrieved from the database, and the message is logged. The rendered content is stored in the cache. When you refresh the page, no further messages should be logged because the view component is never invoked. The content within the cache tag helper is retrieved from the cache instead of being regenerated by the view component.

That leaves the following question: how will you refresh the content if another property or city is added? The `cache` attribute has several attributes that enable you to manage cache expiration:

- `expires-after`—A `TimeSpan` representing the period of time after which the cached item should expire
- `expires-on`—A `DateTimeOffset` representing the absolute time at which the cached entry should expire
- `expires-sliding`—A `TimeSpan` representing the period of time after the last access that the item should expire

The following example uses the `expires-after` attribute to remove the cache item after 1 hour:

```
<cache expires-after="TimeSpan.FromHours(1)">...</cache>
```

It would be ideal to simply refresh the cache any time the content is changed; working directly with the `IMemoryCache` API enables you to do just that, as you will see next.
