Both versions contain a basic configuration for logging. The development version also contains a configuration entry named `DetailErrors` set to `true`. This enables full details of any errors that occur within the application to be rendered to the browser. Host filtering is configured in the production version. You can store pretty much any application configuration information in the app-settings files. Later, you will use them to store a database connection string and email settings.

App-settings files are not the only place you can store configuration information. Many other locations, including environment variables, are supported out of the box, and you can configure your own locations. You will learn more about configuration in chapter 14.

2.2.8 Program.cs

Readers who are familiar with C# programming know that Program.cs provides the entry point to a console application. By convention, it houses a static `Main` method that contains logic for executing the application. This file is no different, except that there is no `Main` method visible. The project template utilizes some newer C# language features, which are introduced in C# 10, one of which is *top-level statements*. This feature allows you to omit the class declaration and `Main` method in Program.cs and start writing executable code. The compiler will generate the class and `Main` method and call your executable code within the method.

The code within the Program.cs file is responsible for configuring, or *bootstrapping*, your web application and starting it. In .NET 5 and earlier, this code was split across two separate files. Much of the application configuration was delegated to a separate class named `Startup`. With the release of .NET 6, the developers behind ASP.NET have tried to reduce the
