amount of complexity that used to exist in basic application configuration. Rather than have code across two files, they have consolidated it into one file, taken advantage of some new C# features to further reduce the boilerplate, and then introduced what they refer to as a *minimal hosting API* to get the minimum code required to bootstrap and run a Razor Pages application down to 15 lines of code. It was nearer to 80 lines of code in the previous version, spread across the two files.

The first line of code creates a `WebApplicationBuilder`:

```
var builder = WebApplication.CreateBuilder(args);
```

Remember that this code will be executed within the compiler-generated `Main` method, so the args passed in to the `CreateBuilder` method are the standard `args` passed in to the `Main` method of any C# console application by whatever process invokes the application.

The `WebApplicationBuilder` is new in .NET 6 and forms part of the minimal hosting API together with another new type: the `WebApplication`, which you will look at shortly. The `WebApplicationBuilder` has several properties, each enabling configuration of various aspects of the application:

- `Environment`—Provides information about the web-hosting environment the application is running in
- `Services`—Represents the application's *service container* (see chapter 7)
- `Configuration`—Enables composition of the configuration providers (see chapter 14)
