- `Logging`—Enables logging configuration via the `ILoggingBuilder`
- `Host`—Supports the configuration of application-host-specific services, including third-party DI containers
- `WebHost`—Enables web server configuration

The application host is responsible for bootstrapping the application, starting it up, and shutting it down. The term *bootstrapping* refers to the initial configuration of the application itself. This configuration includes the following:

- Setting the content root path, which is the absolute path to the directory that contains the application content files
- Loading configuration information from any values passed in to the args parameter, app-settings files, and environment variables
- Configuring logging providers

All .NET applications are configured in this way, whether they are web applications, services, or console applications. On top of that, a web server is configured for web applications. The web server is configured through the `WebHost` property, which represents an implementation of the `IWebHostBuilder` type. The default web server is a lightweight and extremely fast web server named Kestrel. The Kestrel server is incorporated within your application. The `IWebHostBuilder` also configures host filtering and integration with Internet Information Services (IIS), which is the Windows web server.

The `IWebHostBuilder` object exposes several extension methods that enable further configuration of the application. For example, earlier I discussed configuring an alternative to the wwwroot folder as the web root
