`HttpContext` class. The in-process web server that processes the request is responsible for creating an instance of `HttpContext` using details from the actual HTTP request. It provides you, the developer, with access to request data via a formal API, rather than forcing you to parse the HTTP request for this information yourself. The `HttpContext` also encapsulates the response for this particular request. Once the web server has created the `HttpContext`, it is made available to the request pipeline. The `HttpContext` is surfaced throughout the application in various guises, so you can work with its properties as required. Table 2.1 details the main properties of the `HttpContext` and what they represent.

Table 2.1 The `HttpContext` properties

Property	Description
`Request`	Represents the current HTTP request (see table 2.2)
`Response`	Represents the current HTTP response (see table 2.3)
`Connection`	Contains information about the underlying connection for the request, including the port number and the IP address information of the client
`Session`	Provides a mechanism for storing data scoped to a user, while they browse the website
`User`	Represents the current user (see chapters 9 and 10)

The `Request` property is represented by the `HttpRequest` class. Table 2.2 details the main properties of this class and their purpose.

Table 2.2 Primary `HttpRequest` properties
