

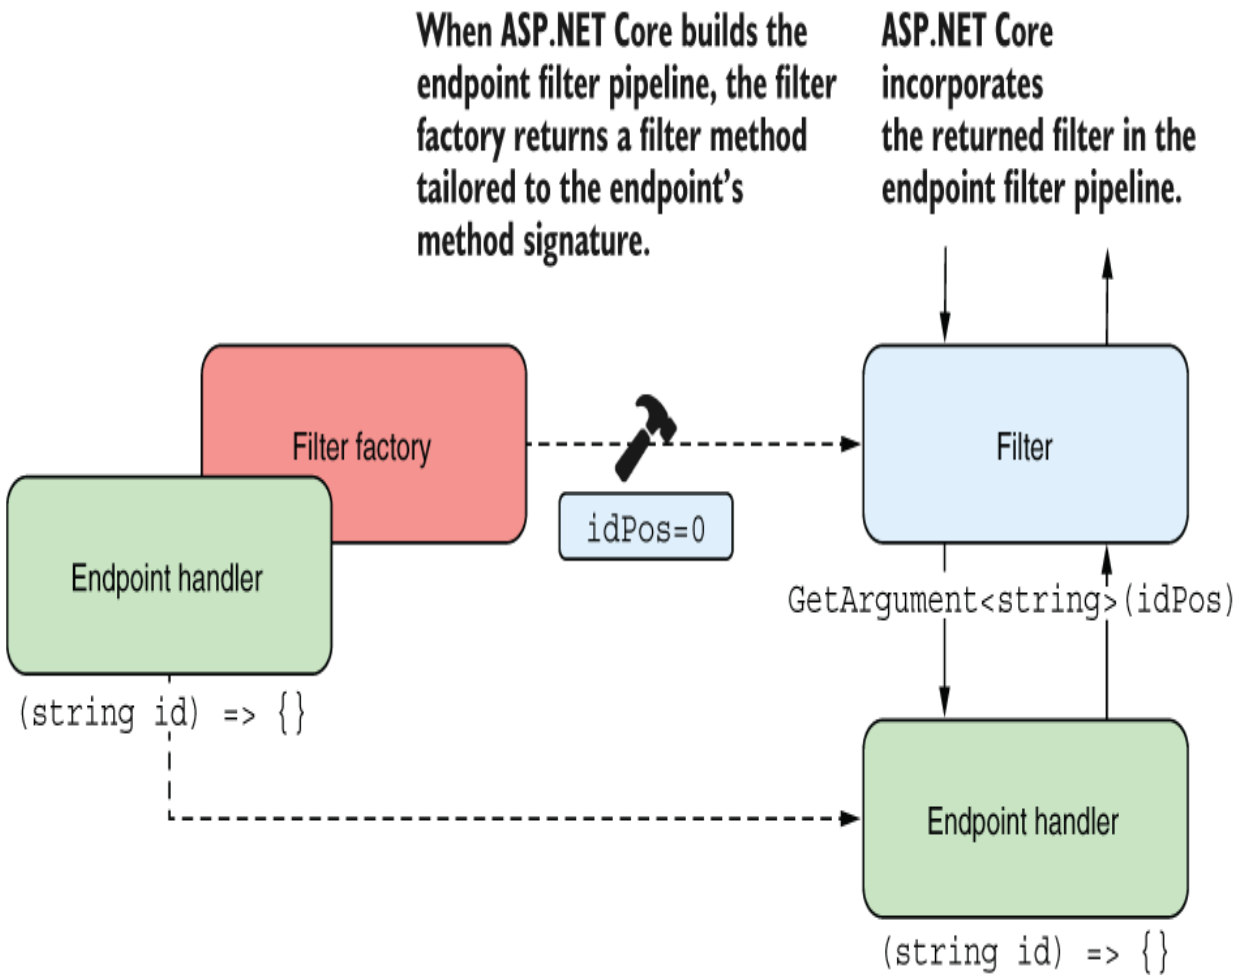

Figure 5.10 A filter factory is a generalized way to add endpoint filters. The factory reads details about the endpoint, such as its method signature, and builds a filter function. This function is incorporated into the final filter pipeline for the endpoint. The build step means that a single filter factory can create filters for multiple endpoints with different method signatures.

Listing 5.11 shows an example of the factory pattern in practice. The filter factory is applied to multiple endpoints. For each endpoint, the factory first checks for a parameter called `id`; if it doesn't exist, the factory returns `next` and doesn't add a filter to the pipeline. If the `id` parameter exists, the factory returns a filter function, which is virtually identical to the filter
