The `WebApplication` stores the registered routes and endpoints in a dictionary that's shared by the `RoutingMiddleware` and the `EndpointMiddleware`.

TIP By default, `WebApplication` automatically adds the `RoutingMiddleware` to the *start* of the middleware and `EndpointMiddleware` to the *end* of the middleware pipeline, though you can override the location in the pipeline by calling `UseRouting()` or `UseEndpoints()`. See section 4.2.3 for more details about automatically added middleware.

At runtime, the `RoutingMiddleware` compares an incoming request with the routes registered in the dictionary. If the `RoutingMiddleware` finds a matching endpoint, it makes a note of which endpoint was selected and attaches that to the request's `HttpContext` object. Then it calls the next middleware in the pipeline. When the request reaches the `EndpointMiddleware`, the middleware checks to see which endpoint was selected and executes the endpoint (and any associated endpoint filters), as shown in figure 6.3.
