collaborative systems where access depends on organizational or social structures.

- ABAC assesses policies based on attributes of the principal, resource, action, and environment. It enables fine-grained, real-time decisions using contextual information such as time, device, or location.
- ReBAC treats policies as relationship data, with access determined by traversing a graph. Policy rules remain the same, while changes to relationships dynamically drive access decisions.
- ABAC treats policies as code evaluated at runtime using current attribute values. This method offers flexible and auditable control but requires careful governance to avoid complexity.
- PBAC combines RBAC, ReBAC, and ABAC by externalizing and dynamically evaluating policy logic. Roles, attributes, and relationships serve as policy inputs, ensuring consistent access control across different systems.
- Different models solve different problems—combining them results in better outcomes. A hybrid approach often provides the best balance of expressiveness, scalability, and maintainability.
