After authoring your schema and policies and modeling your entities, you have options for deploying Cedar in production. Two common options are the Cedar Local Agent and the Amazon Verified Permissions (AVP) API. Both utilize the same Cedar evaluation logic but differ in deployment method, integration complexity, and operational trade-offs.

Cedar Local Agent

Cedar Local Agent (CLA) is an open-source Rust crate that provides a customizable cache for Cedar policies and entities. CLA can operate within or alongside your application, often as a sidecar container or local process. Your Policy Enforcement Point (PEP) sends evaluation requests to it over HTTP.

Pros:

- Low latency—performs a local call instead of a network hop to a remote service.
- Full control over policy and entity lifecycle; functions in any environment.
- No dependence on a public cloud; operates wherever Cedar can run.

Cons:

- You manage the operational workload: deploying, scaling, and updating the agent.
- Requires your own policy or entity distribution system.

Amazon Verified Permissions

Amazon Verified Permissions (AVP) is a fully managed AWS service that hosts Cedar and makes it accessible through AWS APIs. Policies are stored and maintained within the service. Entities are usually stored in a separate AWS data store. Your PEP, often implemented as an AWS Lambda, calls the AVP API.
